Single-trait model

Optimal phenotype moves at speed v

$$w(z,t) = \exp\left[-\sigma^{-1}(z-vt)^2\right]$$

- Recurrent mutations at rate μ
- Constant, finite population size N

The selective environment acts as a sieve.

Multiple traits

The adaptive walk approximation

- Neglect genetic details
- Assume instantaneous fixation
- ⇒ Adaptation can be treated as a stochastic process.

▲□▶ ▲□▶ ▲□▶ ▲□▶ □ のQで

Waiting time to first step

Probability that no mutation of any size has fixed by time *t* is again:

$$F(t) = \exp\left(-\int_{s(\alpha,t)>0} \frac{\Theta p(\alpha)}{2} \lambda_{\alpha} (t-\tau_{\alpha})^2 d\alpha\right)$$

The integral is over all mutations that have a positive selection coefficient at time t (ellipsoid around the current optimum).

Multiple traits

・ロト・(四ト・(川下・(日下))

Assume that the distribution of new mutations, $p(\alpha)$ is multivariate normal.

In the environmentally-limited case, we approximate it by a uniform distribution $p(\alpha) = (2\pi)^{-T/2}$.

Then, the integral in F(t) can be solved to

$$\kappa(t) = t^{T+3} \left(\sqrt{v' \Sigma^{-1} v} \right)^{T+2} \sqrt{\det(\Sigma)} \eta(T) \theta$$

with

$$\eta(T) = \frac{2^{-T/2}}{(T+3)\Gamma(2+T/2)}$$
(1)

◆□▶ ◆□▶ ▲□▶ ▲□▶ ■ ののの

◆□▶ ◆□▶ ◆□▶ ◆□▶ ● ● ● ●

To make further progress, we again consider the environmentally-limited case.

Assume the distribution of new mutations is multivariate normal, and is approximated by a uniform distribution, $p(\alpha) = (2\pi)^{-1/T}$.

Then, after some calculations, the mean size of the first step is

$$\bar{\alpha} = \frac{\mathbf{v}}{||\mathbf{v}||} \gamma^{\frac{1}{T+3}} \Gamma\left(\frac{T+4}{T+3}\right)$$

Multiple traits
