Outline

1. Motivation
2. Variance Swaps and Forward Variances
3. A Model for the Joint Dynamics of an Index and its Variance Swaps
   - Fourier Pricing of VS/VIX Options
   - A Hull-White Type Mixing Formula for Vanilla Options
4. Calibration and Implementation
5. Conclusion
Motivation

- The coexistence of a liquid market for options and volatility derivatives such as VIX options, VIX futures
- A well developed over-the-counter market for options on variance swaps, and
- The use of variance swaps and volatility index futures as hedging instruments

have led to the need for a pricing framework in which volatility derivatives and derivatives on the underlying asset can be priced in a consistent manner.

In order to yield derivative prices in line with their hedging costs, such models should be based on a realistic and consistent joint dynamics of the underlying asset and their variance swaps and match the observed prices of liquid derivatives—futures, calls, puts and variance swaps—used as hedging instruments.
In principle, any continuous-time model with stochastic volatility and/or jumps implies some joint dynamics for variance swaps and the underlying asset price but in practice this joint dynamics can be highly intractable and/or unrealistic (Bergomi 2004).
In principle, any continuous-time model with stochastic volatility and/or jumps implies some joint dynamics for variance swaps and the underlying asset price but in practice this joint dynamics can be highly intractable and/or unrealistic (Bergomi 2004).

Opposed to the modeling of instantaneous (unobservable) volatility, a modeling approach motivated by the availability of variance swap/VIX quotes is proposed in Dupire (1993) and recently developed in Bergomi (2005, 2008), Buehler (2006), and Gatheral (2008), in which volatility risk is modelled through observable volatility indicators, such as spot and forward variance swap rates (or spot VIX and VIX futures),
Motivation: Objectives

We propose an arbitrage-free modeling framework for the joint dynamics of forward variance swap rates along with the underlying index, which

1. captures the information in index option prices by matching the index implied volatility smiles.
2. can reproduce the term structure of variance swap rates
3. captures the information in options on VIX futures by matching their prices/smiles.
4. is compatible with empirical properties of index/ variance swap dynamics, allowing in particular for jumps in volatility and returns (see e.g. Todorov and Tauchen (2010), Jacod and Todorov (2009)) and the type of correlations observed in data.
5. enables efficient pricing of vanilla options, a key point for calibration and implementation of the model.

Conditional Correlation

**Table:** Conditional correlation between the daily returns on S&P 500 and the VIX from September 22nd, 2003 to February 27th, 2009, given the index return $r_t$ is below a threshold.

|       | $r_t < -6.5\%$ | $r_t < -5\%$ | $r_t < -4\%$ | $r_t < -3\%$ | $|r_t| < 0.5\%$ |
|-------|----------------|--------------|--------------|--------------|---------------|
| Unconditional | -0.74 | -0.88 | -0.55 | -0.45 | -0.24 | -0.45 |

**Figure:** Conditional correlation implied by data on S&P 500 and the VIX compared to simulated correlated Gaussian returns with same unconditional correlation of -0.74.
Variance Swaps and Forward Variances

Variance swaps (VS) offer investors an efficient way to take positions in pure volatility/variance.

- At maturity $T$ a VS pays the difference between the annualized realized variance of the log-returns $RV_{t,T}$ less the VS rate $V_t^T$

$$RV_{t,T} - V_t^T = \frac{M}{k} \sum_{i=1}^{k} \left( \log \frac{S_{t_i}}{S_{t_{i-1}}} \right)^2 - V_t^T.$$

where $M$ is the total number of measurement points in one year (i.e. trading days per year (252) if $k$ is the number of trading days between $t$ and $T$).
Variance Swaps and Forward Variances

Variance swaps (VS) offer investors an efficient way to take positions in pure volatility/variance.

- At maturity $T$ a VS pays the difference between the annualized realized variance of the log-returns $RV_{t,T}$ less the VS rate $V_t^T$

\[ RV_{t,T} - V_t^T = \frac{M}{k} \sum_{i=1}^{k} \left( \log \frac{S_{t_i}}{S_{t_{i-1}}} \right)^2 - V_t^T. \]

where $M$ is the total number of measurement points in one year (i.e. trading days per year (252) if $k$ is the number of trading days between $t$ and $T$).

- As $\sup (t_{i+1} - t_i) \rightarrow 0$ the realized variance converges towards the quadratic variation of the log-price

\[ \frac{M}{n} \sum_{i=1}^{n} \left( \log \frac{S_{t_i}}{S_{t_{i-1}}} \right)^2 \xrightarrow{\text{Q}} \frac{1}{T-t} \left( [\log S]_T - [\log S]_t \right). \quad (1) \]
$V_t^T$ is determined such that the VS has zero price at initiation, so taking risk neutral expectation on RHS in (1)

$$V_t^T = \frac{1}{T-t} \mathbb{E} \left( [\log S]_T - [\log S]_t \mid \mathcal{F}_t \right).$$  

The forward variance between time $T_1$ and $T_2$ is defined as

$$V_t^{T_1,T_2} = \frac{1}{T_2-T_1} \mathbb{E} \left( [\log S]_{T_2} - [\log S]_{T_1} \mid \mathcal{F}_t \right)$$

$$= \frac{(T_2-t)V_t^{T_2} - (T_1-t)V_t^{T_1}}{T_2-T_1},$$

where $t < T_1 < T_2$. Notice, $V_t^{T_1,T_2}$ market data since $V_t^{T_1}$ and $V_t^{T_2}$ are.

Take a tenor structure with $T_{i+1} - T_i = \tau$ and define

$$V_t^i \equiv V_t^{T_i,T_{i+1}}.$$

- Forward variances are martingales under the risk neutral measure.
- We model the observables $V_t^i$. 

Thomas Kokholm (ASBSS, AU)

Model: Variance Swap Dynamics

We model the forward variance swap rate as an exponential martingale with a diffusion and jump component:

\[ V_t^i = V_0^i e^{X_t^i} \]

\[ = V_0^i \exp \left\{ \int_0^t \mu_s^i \, ds + \int_0^t \omega e^{-k_1(T_t-s)} \, dZ_s + \int_0^t \int_{\mathbb{R}} e^{-k_2(T_t-s)} x J(dx) \, ds \right\}, \]

where \( J(dx \, dt) \) is a random measure with non-random compensator

\( \nu(dx \, dt) = \nu(dx) \, dt \), \( Z \) a Wiener process, independent of the jump term. To ensure that the above is a martingale, the drift equals

\[ \mu_t^i = -\frac{1}{2} \omega^2 e^{-2k_1(T_t-t)} - \int_{\mathbb{R}} \nu(dx) \left( \exp \left\{ e^{-k_2(T_t-t)} x \right\} - 1 \right). \]

For \( t > T_i \) we let \( V_t^i = V_{T_i}^i \).

- For proper choice of \( \nu \), we know the characteristic function of \( X_{T_i}^i \), so options on VSs can be priced by fast Fourier transform methods (Carr and Madan 1999) \( \rightarrow \) Computationally very efficient.
Model: Index Dynamics

Once the dynamics of forward variance swaps $V_t^i$ for a discrete set of maturities $T_i$, $i = 1..n$ has been specified, we look for a specification of the (risk neutral) dynamics of the underlying asset $(S_t)_{t\geq 0}$ such that:

1. it is consistent with variance swap dynamics:

$$\forall i = 1..n, \quad \frac{1}{T_{i+1} - T_i} E[ \left[ \log S \right]_{T_{i+1}} - \left[ \log S \right]_{T_i} | F_t] = V_t^i \quad (6)$$

2. the model values of calls/puts on $S$ match the observed prices across strikes and maturities.

Typically we need at least two distinct parameters/degrees of freedom in the dynamics of the underlying asset in order to accommodate points 1) and 2).

Bergomi (2005,2008) proposes to achieve this by introducing a random ”local volatility” function which is reset at each tenor date $T_i$ to match the observed value of $V_{T_i}^i$. This leads to a loss of tractability: even vanilla call options need to be priced by Monte Carlo simulation when their maturity $T > T_1$.
Our choice for the stock dynamics is then for $t = T_m, m = 1, ..., n$

$$S_{T_m} = S_0 \exp \left\{ \int_0^{T_m} (r_s - q_s) \, ds + \sum_{i=0}^{m-1} \mu_i (T_{i+1} - T_i) + \sigma_i (W_{T_{i+1}} - W_{T_i}) \right.$$

$$\left. + \sum_{i=0}^{m-1} \int_{T_i}^{T_{i+1}} \int_{\mathbb{R}} u_i (x, V_{T_i}^i) \, J(dxds) \right\},$$

where $\mu_i = -\frac{1}{2} \sigma_i^2 - \int_{\mathbb{R}} v (dx) \left( e^{u_i(x, V_{T_i}^i)} - 1 \right)$, the $\sigma_i$s are stochastic and fixed/revealed at time $T_i$ to match the known $V_{T_i}^i$. The drift terms $\mu_i$ are also stochastic and $\mathcal{F}_{T_i}$-measurable. $J$ in the stock index dynamics is the same as that in the VS dynamics, so the two jump simultaneously but in opposite directions. $u_i$ is a deterministic function of $x$ and $V_{T_i}^i$ chosen to match the observed implied volatility smiles. $W$ is independent of $J$ but $dW_t dZ_t = \rho dt$.

- Presence of a jump component as well as a diffusion component in the underlying asset allows us to satisfy the points 1) and 2).
Fitting the Variance Swaps

Remember

\[ V_t^i = \frac{1}{T_{i+1} - T_i} \mathbb{E} \left( \left[ \log S \right]_{T_{i+1}} - \left[ \log S \right]_{T_i} \mid \mathcal{F}_t \right). \]

In our model we have

\[ V_t^i = \mathbb{E} \left[ \sigma_i^2 \mid \mathcal{F}_t \right] + \mathbb{E} \left[ \int_{\mathbb{R}} u_i (x, V^i_{T_i})^2 \nu(dx) \mid \mathcal{F}_t \right], \]

but since \( V_t^i \) is a martingale we just have to ensure at time \( T_i \) that

\[ V^i_{T_i} = \sigma_i^2 + \int_{\mathbb{R}} u_i (x, V^i_{T_i})^2 \nu(dx). \] (7)

The observed forward variances at times \( T_i \)s can be matched by appropriate choices of the \( \sigma_i \)s, which leaves the parameters in \( u_i \) free to calibrate to option prices.
For the model to be consistent with market prices of call/put options we need to be able to compute efficiently

\[ C(0, S_0, T_m, K) = e^{-\int_0^{T_m} r_s ds} E[(S_{T_m} - K)^+ | \mathcal{F}_0]. \] (8)
Pricing of Vanilla Options

- For the model to be consistent with market prices of call/put options we need to be able to compute efficiently

\[
C(0, S_0, T_m, K) = e^{-\int_0^{T_m} r_s ds} E[(S_{T_m} - K)^+ | \mathcal{F}_0].
\]  

(8)

- Denote by \(\mathcal{F}_t^{(Z,J)}\) the filtration generated by the Wiener process \(Z\) and the Poisson random measure \(J\). By first conditioning on the factors driving the variance swap curve and using the iterated expectation property

\[
C(0, S_0, T_m, K) = e^{-\int_0^{T_m} r_s ds} E[E[(S_{T_m} - K)^+ | \mathcal{F}_{T_m}^{(Z,J)}] | \mathcal{F}_0]
\]  

(9)

we obtain a mixing formula à la Hull-White for valuing call options:
Proposition

The value $C(0, S_0, K, T_m)$ of a European call option with maturity $T_m$ and strike $K$ is given by

$$C(0, S_0, K, T_m) = E^{Z,J}[C^{BS} (S_0 e^{u_m}, K, T_m; \sigma_*)], \tag{10}$$

where $C^{BS}(S, K, T; \sigma)$ denotes the Black-Scholes formula and

$$\sigma_2^* = \frac{1}{T_m} \sum_{i=0}^{m-1} \sigma_i^2 (1 - \rho^2) (T_{i+1} - T_i), \tag{11}$$

$$u_m = \left\{ \sum_{i=0}^{m-1} - \left( \frac{1}{2} \sigma_i^2 \rho^2 + \int_{\mathbb{R}} \left( e^{u_i(x, V_{T_i}^i)} - 1 \right) \nu(dx) \right) (T_{i+1} - T_i) \right\}$$

$$\rho (Z_{T_{i+1}} - Z_{T_i}) \sigma_i + \int_{T_i}^{T_{i+1}} \int_{\mathbb{R}} u_i(x, V_{T_i}^i) J(dx \, ds) \right\}$$
Note that the outer expectation can be computed by Monte Carlo simulation of the $Z$ and $J$: with $N$ simulated sample paths for $Z$ and $J$ we obtain the following approximation

$$C(0, S_0, K, T_m) \simeq \frac{1}{N} \sum_{k=1}^{N} C^{BS}\left(S_0e^{u_m^{(k)}}, K, T_m; \sigma^*(k)\right).$$ (12)
Note that the outer expectation can be computed by Monte Carlo simulation of the $Z$ and $J$: with $N$ simulated sample paths for $Z$ and $J$ we obtain the following approximation

$$C(0, S_0, K, T_m) \approx \frac{1}{N} \sum_{k=1}^{N} C^{BS} \left(S_0 e^{u_m^{(k)}}, K, T_m; \sigma^*(k)\right). \quad (12)$$

Since the averaging is done over the variance swap factors $Z$ and $J$, this is a deterministic function of the parameters in the $u_i$s. This will prove very useful when calibrating the model using option data, since we do not have to run the $N$ Monte Carlo simulations for each calibration trial.
Note that the outer expectation can be computed by Monte Carlo simulation of the $Z$ and $J$: with $N$ simulated sample paths for $Z$ and $J$ we obtain the following approximation

$$C(0, S_0, K, T_m) \sim \frac{1}{N} \sum_{k=1}^{N} C^{BS}\left(S_0 e^{u_m(k)}, K, T_m; \sigma^*(k)\right). \quad (12)$$

Since the averaging is done over the variance swap factors $Z$ and $J$, this is a deterministic function of the parameters in the $u_i$s. This will prove very useful when calibrating the model using option data, since we do not have to run the $N$ Monte Carlo simulations for each calibration trial.

Equation (12) is important since it shows that we are able, in a cost efficient way, to calibrate the model to the entire implied volatility smile for various maturities. In the Bergomi models it is only possible to calibrate to at-the-money slope of the implied volatility (ATM skew).
Fitting the Term Structure of Variance Swaps
Example: Gaussian Jumps

- We specify the Lévy measure as \( \nu(dx) = \lambda f(x) \, dx \), where \( f \) is the density for the normal distribution with mean \( m \) and variance \( \delta^2 \) and \( \lambda \) the intensity of the jumps.

- We let the \( u_i \)s be given by

\[
u_i(x, V^i_{T_i}) = \left( \frac{V^i_{T_i}}{V^i_0} \right)^{\frac{1}{2}} b_i x.
\]

(13)

- This gives us the \( \sigma_i \)s at time \( T_i \)

\[
\sigma_i^2 = V^i_{T_i} - \lambda \frac{V^i_{T_i}}{V^i_0} \left( b_i^2 m^2 + b_i^2 \delta^2 \right).
\]

In order to achieve non-negative values for \( \sigma_i^2 \) we require that

\[
\lambda \left( b_i^2 m^2 + b_i^2 \delta^2 \right) \leq V^i_0.
\]

(14)
Example: Double-Exponential Jumps

- The jump size density is chosen as

\[ f(x) = \left( p\alpha_+ e^{-\alpha_+ x} \mathbf{1}_{x \geq 0} + (1 - p) \alpha_- e^{-\alpha_- |x|} \mathbf{1}_{x < 0} \right) \]  

(15)

where \( p \) denote the probability of a positive jump and \( 1/\alpha_+ \) and \( 1/\alpha_- \) the mean positive and negative jump sizes.

- We take as before

\[ u_i(x, V_{T_i}^i) = \left( \frac{V_{T_i}^i}{V_0^i} \right)^{\frac{1}{2}} b_i x , \]  

(16)

which yields

\[ \sigma_i^2 = V_{T_i}^i - \lambda \frac{V_{T_i}^i}{V_0^i} \left( \frac{2pb_i^2}{\alpha_+^2} + \frac{2(1-p)b_i^2}{\alpha_-^2} \right) . \]

To ensure positive \( \sigma_i \)'s we constrain the calibration by

\[ \lambda \left( \frac{2pb_i^2}{\alpha_+^2} + \frac{2(1-p)b_i^2}{\alpha_-^2} \right) \leq V_0^i. \]  

(17)
In total, we have data from August 20th, 2008 on a range of:

- VIX put and call options for five maturities.
- Call and put options on S&P 500 for six maturities.
- Dividend yield and futures prices on S&P 500, from which we also derive a discount curve.
- Forward 1 month VS rates for various maturities extracted from Bloomberg.
The calibration of the model consists of three steps:

1. First, determine the parameters controlling the VS dynamics by calibration to VIX options using fast Fourier transform methods (here a convexity approximation is performed in order to go from forward VS dynamics to VIX futures dynamics).
The calibration of the model consists of three steps:

1. First, determine the parameters controlling the VS dynamics by calibration to VIX options using fast Fourier transform methods (here a convexity approximation is performed in order to go from forward VS dynamics to VIX futures dynamics).

2. Then, use the parameters from first step simulate $N$ paths of the VSs and store the increments of $Z$, the jump times and jump sizes along with the $V_{T_i}^j$s.
The calibration of the model consists of three steps:

1. First, determine the parameters controlling the VS dynamics by calibration to VIX options using fast Fourier transform methods (here a convexity approximation is performed in order to go from forward VS dynamics to VIX futures dynamics).

2. Then, use the parameters from first step simulate $N$ paths of the VSs and store the increments of $Z$, the jump times and jump sizes along with the $V_{Ti}$s.

3. Now calibrate to options on the stock index recursively by use of (12)

$$C \left( S_0, K, T; u \right) = \frac{1}{N} \sum_{k=1}^{N} C^{BS} \left( S_0 e^{u_m^{(k)}}, K, T; \sigma^* (k) \right).$$
In the calibration steps we minimize the objective function on out-of-the-money options

$$\text{SE} = \sum_{\text{options}} \frac{1}{Q_{\text{Ask}} - Q_{\text{Bid}}} (Q_{\text{Market, Mid}} - Q_{\text{Model}})^2$$  \hspace{1cm} (18)

and we report the corresponding resulting calibration error given by

$$\text{Error} = \frac{1}{\# \{\text{options}\}} \sum_{\text{options}} \max \left\{ \left( Q_{\text{Model}} - Q_{\text{Ask}} \right)^+, \left( Q_{\text{Bid}} - Q_{\text{Model}} \right)^+ \right\} \frac{1}{Q_{\text{Market, Mid}}}.$$  \hspace{1cm} (19)

Exotic Derivatives Examples

The forward straddle has time $T_2$ payoff

$$|S_{T_2} - S_{T_1}|,$$

where we in the pricing example choose the time points equal to $T_1 = 5$ months and $T_2 = 10$ months.

The reverse cliquet has a final time $T_n$ payoff of

$$\max \left\{ 0, C + \sum_{i=1}^{n} \min \left\{ \frac{S_{T_i} - S_{T_{i-1}}}{S_{T_{i-1}}}, 0 \right\} \right\},$$

where the returns are observed monthly, $T_n = 10$ months and $C = 30\%$.

Table: Confidence intervals of prices computed with 2 million simulations.

Conclusion

- A model for the joint dynamics of a set of forward variance swap rates and the underlying index.

- Using Lévy processes as building blocks leads to tractable pricing for VIX futures and options (Fourier) and vanilla call/put options (Hull-White type formula).

- This tractability makes calibration to such instruments feasible and distinguishes our model from (Bergomi 2005, 2008, Gatheral 2008) which require full Monte Carlo pricing of vanilla options.

- Our model reproduces salient empirical features of variance swap dynamics—strong negative correlation of large index moves with VIX moves, positive skew observed in implied volatilities of VIX options—by introducing a common jump component in the variance swaps and the underlying asset.

- Enables to price and hedge payoffs sensitive to forward volatility, consistently with market prices of calls, puts or variance swaps.
