Elementary Landscape Analysis	Elementary Landacape Analysis

Introduction

Landscape: a vertex-weighted graph

• The vertices are points in the search space

- What is an "elementary" landscape?
- \bullet A fitness function f that has a special relationship with the neighborhood operator N with respect to X
- $\bullet \ {\sf Elementary} = \ {\sf ``fundamental \ component''}$

Why is this useful?

- Certain "smooth" properties
- $\bullet\,$ Computation of average neighborhood
- Constraints on plateaus, local optima

Preliminaries

G(X, E)

is the underlying graph induced by $N. \label{eq:N}$ We assume G is regular with vertices of degree d.

 $\boldsymbol{A} \in \mathbb{R}^{|X| \times |X|}$

is the adjacency matrix of G. If x_1 and x_2 are neighbors, $A(x_1,x_2)=1.$

 $\boldsymbol{\Delta} = \boldsymbol{A} - d\boldsymbol{I} \in \mathbb{R}^{|X| \times |X|}$

is the Laplacian of G.

Note: f is a discrete, finite function, $f \in \mathbb{R}^{|X|}$.

On an arbitrary landscape	
• f and N are unrelated	
On an elementary landscape	
The wave equation	
$\Delta f = \lambda f$	
• where λ is a scalar	
 where λ is a scalar In other words, f is an eigenvector of the Laplacian 	
\bullet where λ is a scalar \bullet In other words, f is an eigenvector of the Laplacian	
${\rm \bullet}$ where λ is a scalar ${\rm \bullet}$ In other words, f is an eigenvector of the Laplacian	
${\rm \bullet}$ where λ is a scalar ${\rm \bullet}$ In other words, f is an eigenvector of the Laplacian	
• where λ is a scalar • In other words, f is an eigenvector of the Laplacian	

The Wave Equation: definition 1

 $\boldsymbol{\Delta} f = (\boldsymbol{A} - d\boldsymbol{I})f = k(\bar{f} - f)$

$$\Delta f(x) = \sum_{y \in N(x)} (f(y) - f(x)) = k(\bar{f} - f(x))$$

Average value

$$\begin{split} \sup_{e \in N(x)} \{f(y)\} &= \frac{1}{d} \sum_{y \in N(x)} f(y) \\ &= f(x) + \frac{1}{d} \left(\sum_{y \in N(x)} f(y) - f(x) \right) \\ &= f(x) + \frac{1}{d} \Delta f(x) \\ &= f(x) + \frac{k}{d} \left(\bar{f} - f(x) \right) \end{split}$$

The Components and \bar{f}

Let ${\boldsymbol{C}}$ denote the set of components

 $0 < p_3 < 1$ is the proportion of the components in C that contribute to the cost function for any randomly chosen solution

$$\bar{f} = p_3 \sum_{c \in C} c$$

. i

For the TSP:

$$\bar{f} = \frac{n}{n(n-1)/2} \sum_{w_{i,j} \in C} w_{i,j}$$
$$\bar{f} = \frac{2}{n-1} \sum_{w_{i,j} \in C} w_{i,j}$$

$$\begin{split} \sup_{y \in N(x)} \left\{ f(y) \right\} &= f(x) + \frac{2}{n(n-3)/2} \left(\sum w - f(x) \right) - \frac{2}{n} f(x) \\ &= f(x) + \frac{2}{n(n-3)/2} \left((n-1)/2\bar{f} - f(x) \right) - \frac{2}{n} f(x) \\ &= f(x) + \frac{(n-1)}{n(n-3)/2} (\bar{f} - f(x)) \\ &= f(x) + \frac{k}{d} (\bar{f} - f(x)) \end{split}$$

One of the following is true.

$$\begin{split} f(x) &= \sup_{y \in N(x)} \left\{ f(y) \right\} = \bar{f} \\ f(x) &< \sup_{y \in N(x)} \left\{ f(y) \right\} < \bar{f} \\ f(x) &> \sup_{y \in N(x)} \left\{ f(y) \right\} > \bar{f} \end{split}$$

Properties
Assume
$$f(x) < \overline{f}$$
. Note that $0 < k/d < 1$.
Then $(\overline{f} - f(x))$ must be positive. Thus

$$\sup_{y \in N(x)} \{f(y)\} = f(x) + \frac{k}{d}(\overline{f} - f(x)) > f(x)$$

Properties

Assume $f(x) < \overline{f}$. Note that 0 < k/d < 1.

$$\begin{split} & \underset{y \in N(x)}{\operatorname{avg}} \{f(y)\} - f(x) = \frac{k}{d}(\bar{f} - f(x)) \\ & \frac{k}{d}(\underset{y \in N(x)}{\operatorname{avg}}\{f(y)\} - f(x)) < \underset{y \in N(x)}{\operatorname{avg}}\{f(y)\} + f(x) = \frac{k}{d}(\bar{f} - f(x)) \\ & \frac{k}{d}(\underset{y \in N(x)}{\operatorname{avg}}\{f(y)\} - f(x)) < \frac{k}{d}(\bar{f} - f(x)) \\ & \mathsf{THUS:} \ f(x) < \underset{y \in N(x)}{\operatorname{avg}}\{f(y)\} < \bar{f} \end{split}$$

Properties

When $f(x)>\bar{f}$ and 0< k/d<1 we can similarly show that: $f(x)> \max_{y\in N(x)} \{f(y)\}>\bar{f}$

A Component Based Model

 \boldsymbol{C} is the set of components (e.g. from a cost matrix)

 \boldsymbol{x} is a solution (e.g. a subset of the cost matrix)

Let $\left(C-x\right)$ denote the set of components, excluding those in x

For a move, we then define: $0 < p_1 < 1$ is the proportion of components in x that change $0 < p_2 < 1$ is the proportion of components in (C - x) that change

<section-header><section-header><section-header><text><text><equation-block><text>

This computation also can be expressed as a 2-dimensional matrix ${\cal M}$ with d rows and $|{\cal C}|$ columns.

For a 5 city TSP

Graph Coloring
The Components are edges in the graph. Assume r colors, $\left V\right $ vertices.
$p_1 = \frac{2(r-1)}{ V (r-1)}$
$p_2 = \frac{2}{ V (r-1)}$
$p_{3} = 1/r$
$\sup_{y \in N(x)} \{f(y)\} = f(x) - p_1 f(x) + p_2 ((1/p_3 \bar{f}) - f(x))$
$= f(x) + \frac{2r}{ V (r-1)}(\bar{f} - f(x))$

Min-Cut Graph Partitioning

The Components are edges in the graph. Assume r colors, $\left|V\right|$ vertices.

$$p_3 = \frac{n/2}{n-1} = \frac{n^2/4}{|C|}$$
$$\bar{f} = p_3 \sum_{c \in C} c = \frac{n}{2(n-1)} \sum_{e_{i,j} \in E} w_{i,j}$$
$$p_1 = \frac{2(n/2-1)}{n^2/4} = \frac{n-2}{n^2/4} = \frac{\alpha}{d}$$
$$p_2 = \frac{n}{n^2/4} = \frac{\alpha}{d}$$

Min-Cut Graph Partitioning

$$\begin{aligned} \sup_{y \in N(x)} \{f(y)\} &= f(x) - p_1 f(x) + p_2 (1/p_3(\bar{f} - f(x))) \\ &= f(x) - \frac{n-2}{n^2/4} f(x) + \frac{n}{n^2/4} \left[\frac{2(n-1)}{n} \bar{f} - f(x) \right] \\ &= f(x) + \frac{2(n-1)}{n^2/4} (\bar{f} - f(x)) \end{aligned}$$

where k=2(n-1) and the neighborhood size is $d=n^2/4. \label{eq:k}$ Grover simplifies this to obtain:

$$\sup_{y \in N(x)} \{f(y)\} = f(x) + \frac{8(n-1)}{n^2} (\bar{f} - f(x))$$

Partial Neighborhoods for Min-Cut

Partial Neighborhoods for Min-Cut

Theorem

Let $n_{\rm L}$ count the number of vertices in the LHS which have no edges that connect to the right hand size.

Let n_{R} count the number of vertices in the RHS which have no edges that connect to the right hand size.

There are $n_L \ x \ n_R$ vertex pairs that cannot be yield an improvement.

Let d^\prime denote the size of the new neighborhood.

Let W^\prime represent the sum of all the weights that are eliminated when these moves are excluded.

A partial neighborhood $N^\prime(x)$ exists for the Min-Cut Graph Partitioning problems such that

$$\begin{split} & \arg\{f(y)\} = f(x) - \frac{2n-2}{d'}f(x) + \frac{n(\sum_{e_{i,j} \in E} w_{i,j}) - W'}{d'} \\ & \text{where } d' = n^2/4 - |n_L||n_r| \\ & \text{and } W' = |n_L| \sum_{i \in V, x \in n_R} w(i,x) + |n_R| \sum_{i \in V, x \in n_L} w(i,x) \end{split}$$

Partial Neighborhoods for Min-Cut

A vector Weights(x) can be precomputed that stores the sum of the weights associated with edges incident on vertex x. The information needed to compute W' is found in the vector Weights(i) since

$$\begin{array}{ll} \mbox{If } x\in n_L \mbox{ then } & \sum_{i\in V} w(i,x) = Weights(x) \\ \\ \mbox{If } x\in n_R \mbox{ then } & \sum_{i\in V} w(i,x) = Weights(x) \end{array}$$

Main insight #1: Matrices as operators	
--	--

Any $|X|\times |X|$ matrix ${\pmb M}$ can be characterized as an operator on the space of real functions over X.

$$Mf = g$$
 $M: \{f: X \to \mathbb{R}\} \to \{f: X \to \mathbb{R}\}$

Consider the matrix vector product Af = g.

$$x \rightarrow \begin{bmatrix} 0 & 1 & 1 & 0 & 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 1 & 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 1 & 0 & 0 & 1 & 0 \\ 0 & 1 & 1 & 0 & 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 & 0 & 1 & 1 & 0 \\ 0 & 1 & 0 & 0 & 1 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 & 1 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 & 0 & 1 & 1 & 0 \end{bmatrix} \begin{bmatrix} 3 \\ 2 \\ 4 \\ 1 \\ 1 \\ 7 \\ 5 \\ 8 \end{bmatrix} = \begin{bmatrix} 7 \\ 11 \\ 9 \\ 14 \\ 15 \\ 11 \\ 13 \\ 13 \end{bmatrix} \leftarrow g(x)$$

Image of f under A is a function g(x) that gives the sum of f values over the neighbors of x (the sifting property).

Main insight #2: Eigenfunctions of the adjacency

Want a set of basis functions that allow us to study the relationship between the neighborhood graph and the fitness function.

$$f(x) = \sum a_i \varphi_i(x)$$

where a_i is an "amplitude" and $\varphi_i: X \to \mathbb{C}$ is an eigenfunction of A.

An eigenfunction of ${\pmb A}$ is any function $\varphi:X\to\mathbb{C}$ that satisfies the equation $\bigl({\pmb A}\varphi\bigr)(x)={\pmb A}\varphi(x)=\lambda\varphi(x)$

for a constant λ .

What does this have to do with elementary landscapes?	
Parall the "unive" equation	
k	
$\sup_{y \in N(x)} \{ f(y) \} = f(x) + \frac{\kappa}{d} (\bar{f} - f(x)) $ (*)	
$\sup_{y \in N(x)} \{f(y)\} = \frac{1}{d} \sum_{y \in N(x)} f(y) = \frac{1}{d} g(x) = \frac{1}{d} \mathbf{A} f(x)$	
(the last equivalence follows by the sifting property)	
So putting this with $(*)$ above, we get	

$$\mathbf{A}f(x) = (d-k)f(x) + (k\bar{f})$$

So if a function obeys the wave equation... it is (up to an additive constant) an eigenfunction of the adjacency matrix of ${\cal G}$

Using the analysis

Computing statistics over regions (Sutton, Whitley & Howe 2012)

Approximating the fitness distribution (Sutton, Whitley & Howe 2011)

Finding good mutation rates (Chicano & Alba 2011)

 $\ensuremath{\mathsf{Providing}}$ fitness bounds on the existence of certain neighborhood features

Computing the correlation structure

Designing search algorithms and heuristics

Fitness functions over bitstrings						
Spectral decomposition of $oldsymbol{A}$						
Write $A = WDW^{-1}$ where D is a diagonal matrix The columns of W are eigenvectors of A						
For Hamming operator, $oldsymbol{A}$ is the hypercube adjacency $\Rightarrow oldsymbol{W}$ is the well-known Walsh matrix.						
The 2^n columns of W correspond to the Walsh functions						
$\psi_i: \{0,1\}^n \to \mathbb{R}$						
For Hamming adjacency, the Walsh functions obey						
$oldsymbol{A}\psi_i(x)=\lambda_i\psi_i(x)$						

Fitness functions over bitstrings

 \pmb{W} is an orthogonal matrix, so any real function f over $\{0,1\}^n$ can be written as a linear combination of Walsh functions

$$f(x) = \sum_{i=1}^{2^n} w_i \psi_i(x)$$

For MAX-k-SAT, most coefficients w_i vanish

• when the length-*n* binary representation of *i* has greater than *k* bits (due to Rana, Heckendorn, Whitley 1998)

Thus there are are ${\cal O}(2^k)$ nonzero coefficients, and they can be computed in time ${\cal O}(m2^k).$

Hoos & Stützle (2004) characterized the search space by empirically sampling and determining the frequency of search positions

On MAX-3-SAT, they could not find any *interior plateau* states.

Correlation structure

Background

Dynamics of polynucleotide folding landscapes, interest in TSP (Fontana et al., 1989)

TSP (Stadler & Schnabl, 1992)

Graph bipartitioning (Stadler & Happel, 1992)

Idea for problem classification (Angel & Zissimopolous, 2000)

MAX-k-SAT (Sutton, Whitley & Howe, 2009)

Quadratic Assignment Problem (Chicano, Luque & Alba, 2012)

Correlation structure						
Random walk transition matrix						
$T = \frac{1}{n} A$						
Random walk process estimates the following equation						
$r(s) = \frac{\langle f, T^s f \rangle - \langle 1, f \rangle^2}{\langle f, f \rangle - \langle 1, f \rangle^2}$						
Replace f with the expansion						
Elementary Landscape Analysis						

mma		
is an eigenvector of the	random walk transition matrix T	
is all eigenvector or the		
	$T\psi_i = \lambda_i \psi_i$	
here $\lambda_i = \left(1 - \frac{2\langle i, i \rangle}{n}\right)$.		

$$f(x) = \sum w_i \psi_i(x)$$

we are actually writing the fitness function in terms of the eigenbasis of \boldsymbol{T}

Correlation structure
Remark. We have the following identities:

$$\langle f, f \rangle = \sum_{i} w_{i}^{2} \qquad \langle f, T^{s} f \rangle = \sum_{i} \lambda_{i}^{s} w_{i}^{2} \qquad \langle \mathbf{1}, f \rangle = w_{0}$$

$$\langle f, f \rangle = \langle \sum_{i} w_{i} \psi_{i}, \sum_{j} w_{j} \psi_{j} \rangle$$

$$= \sum_{i} \sum_{j} w_{i} w_{j} \langle \psi_{i}, \psi_{j} \rangle$$

$$= \sum_{i} \sum_{j} w_{i} w_{i} \langle \psi_{i}, \psi_{j} \rangle$$
since $\{\psi_{i}\}$ is an orthogonal basis

Correlation structure	
Remark. We have the following iden	tities:
$\langle f,f angle = \sum_i w_i^2 \qquad \langle f, \mathbf{T}^s f angle = \sum_i \lambda_i$	$\langle s_i^s w_i^2 \qquad \langle {f 1}, f angle = w_0$
$\begin{split} \langle f, \mathbf{T}^s f \rangle &= \langle \sum_i w_i \psi_i, \mathbf{T}^s \sum_j w_j \psi_j \rangle \\ &= \sum_i \sum_j w_i \lambda_j^s w_j \langle \psi_i, \psi_j \rangle \\ &= \sum_i \lambda_i^s w_i^2 \end{split}$	since $\{\psi_i\}$ is an eigenbasis since $\{\psi_i\}$ is an orthogonal basis

Correlation structure				
Remark. We have the following identities:				
$\langle f, f \rangle = \sum_{i} w_{i}^{2} \qquad \langle f, T^{s} f \rangle = \sum_{i} \lambda_{i}^{s} w_{i}^{2} \qquad \langle 1, f \rangle = w_{0}$				
$\langle {f 1},f angle = \langle {f 1},\sum_i w_i\psi_i angle$				
$=w_0$				
Elementary Landscape Analysis				

Correlation structure	
This gives exact autocorrelation function $\sum \chi^{*} w^{2}$	
$r(s) = \frac{\sum_{i \neq 0} r_i w_i}{\sum_{j \neq 0} w_j^2}$	
where $\lambda_i = \left(1 - rac{2\langle i,i angle}{n} ight).$	

Recall for MAX- $k\mbox{-}{\rm SAT}$ all nonzero w_i can be computed in O(m) time.

Neighborhoods that result in elementary landscapes

$$\label{eq:Max-k-SAT} \begin{split} \mathrm{Max}\text{-}k\text{-}\mathrm{SAT} &- \mathrm{neighborhood} \text{ operator } \mathrm{is} \text{ Hamming operator, i.e., flip} \\ \mathrm{each \ bit:} \\ N\big((0,1,0)\big) &= \{(1,1,0),(0,0,0),(0,1,1)\}. \end{split}$$

Together, f and $N~{\rm do}~{\rm not}$ form an elementary landscape, rather we have been expressing f as a linear combination of elementary landscapes.

Questions

- \bullet Can we find a new neighborhood operator N' such that f and N' yield an elementary landscape?
- If so, how is this useful?

Max-2-Sat

Proof (continued).

Clause indicator function $c_i : \{0, 1\}^n \to \{0, 1\}.$

 $\sum_{y \in N'(x)} c_i(y) = 3(1 - c_i(x)) + (|N'(x)| - 1)c_i(x) = 3 + (n - 3)c_i(x).$

Since $f(x) = \sum_{i=1}^m c_i(x)$, we have

$$\sum_{y \in N'(x)} f(y) = \sum_{i=1}^{m} (3 + (n-3)c_i(x)) = 3m + (n-3)f(x).$$

Thus N^\prime and f satisfy the "wave equation".

Max-2-Sat

Define $A_{i,j}$ be the 3-set of clauses defined on two variables \boldsymbol{v}_i and \boldsymbol{v}_j

 $A_{i,j} = \{ (\neg v_i \lor \neg v_j), (\neg v_i \lor v_j), (v_i \lor \neg v_j) \}.$

Construct a ${\rm MAX-2\-SAT}$ instance on 2q variables by taking the union of q 3-sets of clauses

$$A_{1,2} \cup A_{3,4} \cup \cdots \cup A_{2q-1,2q}.$$

Thus for this instance, m = 3q.

Consider $\hat{x} = (111\cdots 1)$ (no improving Hamming neighbors)

Since \hat{x} satisfies 2 clauses in each set $A_{i,j}$, we have

$$f(\hat{x}) = 2q = \frac{2}{3}m < \frac{3}{4}m.$$

Max-2-Sat

It follows that, when using the Hamming (flip) operator on $\rm MAX-2-SAT$ there can be local optima with inferior fitness to all local optima on the landscape induced by the new operator.

Local search using N^\prime is a polynomial-time 3/4-approximation algorithm for Max-2-Sat.

This result was also used to show that the (1+1) EA is a randomized fixed-parameter tractable algorithm for the standard parameterization of $\rm Max-2-Sat$ (Sutton, Day, & Neumann, GECCO 2012) \Rightarrow First connection of elementary landscape analysis to runtime analysis.

Constant Time Steepest Descent

Constant Time Steepest Descent

Let vector \boldsymbol{w}' store the Walsh coefficients including the sign relative to solution $\boldsymbol{x}.$

 $w_i'(x) = w_i \psi_i(x)$

Flip bit p such that $y_p \in N(x).$ Then

if
$$p \subset i$$
 then $w'_i(y_p) = -w'_i(x)$
otherwise $w'_i(y_p) = w'_i(x)$

For MAX-kSAT and NK-Landscapes flipping one bit changes the sign of only a constant number of Walsh coefficients.

Construct a vector \boldsymbol{S} such that

$$S_p(x) = \sum_{\forall b = x \in I} w'_b(x)$$

In this way, all of the Walsh coefficients whose signs will be changed by flipping bit p are collected into a single number $S_p(x)$.

Constant Time Steepest Descent

Lemma 1.

Let $y_p \in N(x)$ be the neighbor of string x generated by flipping bit p. Then $f(y_p) = f(x) - 2(S_p(x)).$

If $p\subset b$ then $\psi_b(y_p)=-1(\psi_b(x))$ and otherwise $\psi_b(y_p)=\psi_b(x).$ For each Walsh coefficient that changes, the change is $-2(w_b'(x)).$

Corollary: For all bit flips j, $f(y_j)=f(x)-2(S_j(x))$. Thus, $S_j(x)$ can be used as a proxy for $f(y_j)$; f(x) is constant as j is varied. Maximizing $S_j(x)$ minimizes the neighborhood of f(x).

Constant Time Steepest Descent

To make this easy, assume we have an NK-Landscape or $\mathsf{MAX}\text{-}\mathsf{kSAT}$ problem such that every variable occcurs exactly the same number of times.

This case is easy to analysis, but also exactly corresponds to the average complexity case (with mild restrictions on the frequence of bit flips).

Assume each variable appears kc time.

For MAX-kSAT c is the clause variable ratio. For NK-landscapes c = 1.

Constant Time Steepest Descent

The locations of the updates are obvious

When one bit flips, it impacts kc subfunctions. There are k(k-1) pairings of bits in each subfunction. Thus there are ck(k-1) total bits affected by a bit flip.

Also at most ck(k-1) terms in vector S change.

When one bit flips, it impacts at most $2^{k-1}-1$ Walsh coefficients in any subfunction. If a bit appears in exactly kc functions, then at most $ck(2^{k-1}-1)$ nonlinear Walsh coefficients change. Thus, the update take O(1) time.

'Old" and "New" improving moves

A "new" improving move must be a new updated locations in S. Checking these takes ${\cal O}(1)$ time on average.

There can be previously discovered "old" moves stored in a buffer. Here we approximate steepest descent.

If there are less than ck(k-1) old moves items in the buffer we check them all. If there are more than ck(k-1) old moves in the buffer, we sample ck(k-1) moves and select the best old move.

We then select either the best new move or the (approximate) best old move. Total cost: at most 2ck(k-1)+1 comparisons, which is ${\cal O}(1)$ But normally there are few improving moves.

Next Ascent

If we want to do Next Ascent instead of Steepest Ascent, we just all of the improving moves into a buffer and pick one. Again, this takes ${\cal O}(1)$ time.

Identifying Local Optima

update is an improving move.

If there are no improving moves, the point is a local optimum. The point is automatically identified: there are no "old" improving moves and no

Steepest Descent over Neighborhood Means

We have the vector S such that

$$S_p(x) = \sum_{\forall b, \ p \subset b} w'_b(x)$$

Also construct the vector \boldsymbol{Z} such that

$$Z_p(x) = \sum_{\forall b, \ p \subset b} \quad order(b) \ w'_b(x)$$

Note that ${\cal S}$ and ${\cal Z}$ and ${\cal U}$ all update at exactly the same locations.

Lemma 2.

$$Avg(N(y_p)) = Avg(N(x)) - 2(S_p(x)) + \frac{4}{N}Z_p(x)$$

Steepest Descent over Neighborhood Means

Let
$$U_p(x) = -2(S_p(x)) + \frac{4}{N}Z_p(x)$$

 $Avg(N(y_p)) = Avg(N(x)) + U_p(x)$ The vector U(x) can now be used as a proxy for Avg(N(x)) Maximizing $U_p(x)$ minimizes the neighborhood of $Avg(N(y_p)).$

The locations of the updates are obvious

$U_1(y_p)$	=	$U_1(x)$
$U_2(y_p)$	=	$U_2(x)$
$U_3(y_p)$	=	$U_3(x) + Update$
$U_4(y_p)$	=	$U_4(x)$
$U_5(y_p)$	=	$U_5(x)$
$U_6(y_p)$	=	$U_6(x)$
$U_7(y_p)$	=	$U_7(x)$
$U_8(y_p)$	=	$U_8(x) + Update$
$U_0(u_n)$	=	$U_0(x)$

Search on an NKq-Landscape

Search on an NKq-Landscape

- And NKq-Landscape generates subfunctions using only \boldsymbol{q} values. For q = 2 there are many plateaus and equal moves. 1. f(x) versus Avg(N(x))

- 2. Steepest Ascent versus Next Ascent 3. Random Walk Restart (with O(1) cost) versus Hard Random Restart (with O(N) cost)

Conclusions

- Elementary landscapes provide an interesting tool for analyzing search in combinatorial optimization
- Linear algebraic approach to formalizing "landscape" concept for discrete problems
- Ongoing research to connect search space topology to algorithm dynamics
